H you are now a professional Python data Analyst, and I want you to explain the code I will provide and explain the code line by line as an absolute beginner.

G Of course, I'd be happy to help you understand a Python code snippet. Please provide the code you'd like me to explain, and I'll go through it line by line, breaking it down for you as if you were an absolute beginner.

H
```
import numpy as np
import pandas as pd
import matplotlib.pyplot as plt # visualizing data
%matplotlib inline
import seaborn as sns
```

G Certainly! This code snippet appears to be setting up the environment for data analysis and visualization in Python using popular libraries like NumPy, pandas, Matplotlib, and Seaborn. Let's go through it line by line:

1. `import numpy as np` : This line imports the NumPy library and gives it the alias "np." NumPy is a powerful library for numerical operations in Python, often used for handling arrays and matrices.
2. `import pandas as pd` : This line imports the pandas library and gives it the alias "pd." Pandas is used for data manipulation and analysis. It provides data structures like DataFrames for handling tabular data.
3. `import matplotlib.pyplot as plt` : This line imports the pyplot module from the Matplotlib library and gives it the alias "plt." Matplotlib is a widely used library for creating static, animated, or interactive visualizations in Python.
4. `%matplotlib inline` : This is called a magic command in Jupyter Notebook or Jupyter Lab. It's used to display Matplotlib plots directly within the Jupyter Notebook or Lab environment, making it more convenient for data analysis.
5. `import seaborn as sns` : This line imports the seaborn library, which is built on top of Matplotlib and provides a higher-level interface for creating aesthetically pleasing statistical visualizations. Seaborn is often used to enhance the default Matplotlib plots with better styling.

This code doesn't perform any specific data analysis or visualization tasks by itself but rather sets up the necessary libraries and environment for you to perform data analysis and create visualizations in Python using NumPy, pandas, Matplotlib, and Seaborn. Once these libraries are imported and the environment is set up, you can proceed with your data analysis tasks, loading data, performing calculations, and creating visualizations.

- 0 / 0 **H**
```
# import csv file
df = pd.read_csv('Diwali Sales Data.csv', encoding='unicode_escape')
```

G This code is reading data from a CSV (Comma Separated Values) file named "Diwali Sales Data.csv" and storing it in a pandas DataFrame called 'df'. Let's break down this line:

1. `df =` : `pd.read_csv('Diwali Sales Data.csv', encoding='unicode_escape')` :
   - `df` : This is a variable name that you've chosen to represent the DataFrame in Pandas. a DataFrame is a two-dimensional, size-mutable, and potentially heterogeneous tabular data structure with labeled axes (rows and columns).
   - `pd` : This is the alias you assigned to the pandas library when you imported it earlier in your code.
   - `read_csv()` : This is a pandas function used to read data from a CSV file and create a DataFrame. It's used here to load the data from the CSV file into a DataFrame.
   - `'Diwali Sales Data.csv'` : This is the name of the CSV file you want to read. Make sure that this file exists in the same directory as your Python script or specify the full path if it's located elsewhere.
   - `encoding='unicode_escape'` : This parameter specifies the character encoding used in the CSV file. In this case, 'unicode_escape' is specified, which is a common encoding for handling various character sets and escape sequences. It's often used when dealing with CSV files that have non-standard or special characters.

So, this line of code reads the data from the 'Diwali Sales Data.csv' file, decodes it using the specified encoding, and stores it in the 'df' DataFrame. After executing this line, you can manipulate and analyze the data in the 'df' DataFrame using pandas' functionality.

H df.shape

G The `df.shape` command is used to retrieve the dimensions of a DataFrame `df` . It returns a tuple containing two values:

1. The number of rows in the DataFrame.
2. The number of columns in the DataFrame.

For example, if you execute `df.shape` and it returns `(100, 5)` , it means that your DataFrame `df` has 100 rows and 5 columns.

This information can be useful when you're working with data because it allows you to quickly check the size of your dataset, which can be important for various data analysis and manipulation tasks.

H df.head(8)

G The `df.head(8)` command is used to display the first 8 rows of the DataFrame `df` . It allows you to quickly inspect the top portion of your dataset to get an idea of the data looks like and to check if it was loaded correctly. Here's what this command does:

- `df` : This is the DataFrame you created earlier, containing your data from the CSV file.
- `.head(8)` : This is a method of the DataFrame `df` . It returns a new DataFrame containing the first 8 rows of the original DataFrame. By default, if you don't specify a number in the parentheses, it returns the first 5 rows.

When you execute `df.head(8)` , you'll see the first 8 rows of your dataset, which can be helpful for initial data exploration and understanding the structure of your data. It's often used to quickly check the data's format, column names, and some sample data points.

H df.info()

G The `df.info()` command is used to retrieve summary information about the DataFrame `df` . It provides various details about the DataFrame's structure and contents. Here's what this command does and what kind of information it typically displays:

- `df` : This is the DataFrame you've been working with.
- `.info()` : This is a method of the DataFrame `df` that displays essential information about the DataFrame.

When you execute `df.info()` , it typically shows the following information:

1. The number of non-null (non-missing) entries in each column: This gives you an idea of whether there are any missing values in your dataset.
2. The data type of each column: This indicates the type of data stored in each column, such as integers, floating-point numbers, strings, etc.
3. The total memory usage: This shows how much memory the DataFrame is using, which can be useful for optimizing memory usage when working with large datasets.
4. The count of columns: This tells you how many columns are present in the DataFrame.

For example, the output might look like this:

```
bash                                                    Copy code
>class 'pandas.core.frame.DataFrame'>
RangeIndex: 1000 entries, 0 to 999
Data columns (total 5 columns):
 Column1   1000 non-null int64
 Column2   1000 non-null float64
 Column3   1000 non-null object
 Column4   1000 non-null int64
 Column5   1000 non-null object
dtypes: float64(1), int64(1), object(3)
memory usage: 39.0 KB
```

In this example, you can see that the DataFrame has 1000 rows and 5 columns. It also provides information about the data types and memory usage for each column. This summary is helpful for understanding the basic characteristics of your dataset and can guide you in further data analysis and preprocessing.

H df.drop(['Status', 'unnamed1'], axis=1, inplace=True)

G The `df.drop(['Status', 'unnamed1'], axis=1, inplace=True)` command is used to remove specified columns from the DataFrame `df` . Let's break down what each part of this command does:

- `df` : This is the DataFrame you've been working with.
- `.drop()` : This is a method of the DataFrame `df` used to remove specified rows or columns.
- `['Status', 'unnamed1']` : This is a list of column names that you want to drop from the DataFrame. In this case, you're removing two columns: 'Status' and 'unnamed1'.
- `axis=1` : This parameter specifies that you want to drop columns (as opposed to rows). The value `1` refers to columns, while `0` would refer to rows.
- `inplace=True` : This parameter specifies that you want to modify the DataFrame `df` in-place, meaning the changes will be made directly to the DataFrame without creating a new copy. If `inplace` is set to `False` (or not specified), a new DataFrame with the specified columns removed would be returned, and the original DataFrame `df` would remain unchanged.

So, when you execute `df.drop(['Status', 'unnamed1'], axis=1, inplace=True)` , it will remove the 'Status' and 'unnamed1' columns from the DataFrame `df` in-place. After this operation, the DataFrame `df` will no longer contain these two columns.

H pd.isnull(df)

G The `pd.isnull(df)` command is used to check for missing (null or NaN) values in a DataFrame `df` . When you run this command, it returns a DataFrame of the same shape as `df` , where each element is a boolean value indicating whether the corresponding element in the original DataFrame `df` is missing (True) or not missing (False).

Here's what this command does:

- `pd` : This is the pandas library.
- `.isnull()` : This is a method of a DataFrame (in this case, `df`) that checks for missing values.

When you execute `pd.isnull(df)` , it will return a DataFrame with the same shape as `df` , where each cell contains either `True` if the corresponding cell in `df` is missing or `False` if it's not missing.

This can be useful for identifying and handling missing data in your dataset, as you can use the resulting DataFrame to locate and manipulate missing values as needed.

H pd.isnull(df).sum()

G The `pd.isnull(df).sum()` command is used to count the number of missing (null or NaN) values in each column of the DataFrame `df` . It returns a Series object that contains the count of missing values for each column. Here's what each part of this command does:

- `pd` : This is the pandas library.
- `.isnull()` : This part of the command creates a DataFrame of the same shape as `df` , where each element is `True` if the corresponding element in the original DataFrame `df` is missing (null), and `False` otherwise.
- `.sum()` : This is a method applied to the DataFrame created by `.isnull()` . When used with a DataFrame, `.sum()` calculates the sum of `True` values along each column. In this context, it counts the number of missing values in each column.

So, when you execute `pd.isnull(df).sum()` , you'll get a Series that shows the count of missing values for each column in the DataFrame `df` . The information is valuable for assessing the extent of missing data in your dataset and deciding how to handle it during data preprocessing.

H df.dropna(inplace=True)

G The `df.dropna(inplace=True)` command is used to remove rows containing missing (NaN) values from the DataFrame `df` . Let's break down what each part of this command does:

- `df` : This is the DataFrame you've been working with.
- `.dropna()` : This is a method of the DataFrame `df` used to remove rows with missing values.
- `inplace=True` : This parameter specifies that you want to modify the DataFrame `df` in-place, meaning the rows containing NaN values will be removed directly from the DataFrame, and the changes will be applied to the original DataFrame. If `inplace` is set to `False` (or not specified), a new DataFrame with rows containing NaN values removed would be returned, and the original DataFrame `df` would remain unchanged.

So, when you execute `df.dropna(inplace=True)` , it will remove all rows in the DataFrame `df` that contain at least one missing (NaN) value. After this operation, `df` will be modified to exclude these rows. This can be useful for cleaning your data by removing rows with incomplete or missing information.

H df['Amount'] = df['Amount'].astype('int')

G The `df['Amount'] = df['Amount'].astype('int')` command is used to change the data type of the 'Amount' column in the DataFrame `df` to integer (int). Let's break down what each part of this command does:

- `df` : This is the DataFrame you've been working with.
- `['Amount']` : This part of the command specifies the column you want to modify, which is 'Amount' in this case.
- `.astype('int')` : This is a method applied to the 'Amount' column. It's used to cast the data type of the column to the specified type, which is 'int' for integer in this case.

So, when you execute `df['Amount'] = df['Amount'].astype('int')` , it converts the 'Amount' column from its previous data type (likely a floating-point number or string) to integers. This can be helpful when you want to work with the 'Amount' column as integers for mathematical operations or analysis that require integer data types.

H df['Amount'].dtypes

G The `df['Amount'].dtypes` command is used to check the data type of the 'Amount' column in the DataFrame `df` . Specifically, it returns the data type of that specific column. Here's what each part of this command does:

- `df` : This is the DataFrame you've been working with.
- `['Amount']` : This part of the command specifies the column you want to examine, which is 'Amount' in this case.
- `.dtypes` : This is an attribute of a pandas Series (or DataFrame) that provides the data type of the Series (or columns).

When you execute `df['Amount'].dtypes` , it will return the data type of the 'Amount' column. For example, it might return something like `dtype('int64')` , which indicates that the 'Amount' column is of data type 'int64' (64-bit integer). This information is useful for verifying the data types of columns in your DataFrame, which can be important for data analysis and manipulation.

H df.rename(columns={'Marital_Status':'Shaadi'})

G The `df.rename(columns={'Marital_Status': 'Shaadi'})` command is used to rename a column in the DataFrame `df` . Let's break down what each part of this command does:

- `df` : This is the DataFrame you've been working with.
- `.rename(columns={'Marital_Status': 'Shaadi'})` : This is a method of the DataFrame `df` used to rename columns. Inside the `columns` parameter, you provide a dictionary where the keys are the current column names, and the values are the new column names you want to assign.

In this specific example, you are renaming the 'Marital_Status' column to 'Shaadi'. After executing this command, the DataFrame `df` will have the 'Marital_Status' column name changed to 'Shaadi'. The rest of the DataFrame's structure and data will remain unchanged. This can be useful when you want to give a more descriptive or meaningful name to a column in your dataset.

H df.describe()

G The `df.describe()` command is used to generate descriptive statistics for the columns in a DataFrame `df` . When you execute this command, it provides various statistical measures for each numerical column in the DataFrame. Here's what this command does:

- `df` : This is the DataFrame you've been working with.
- `.describe()` : This is a method applied to the DataFrame `df` . It computes summary statistics for the numerical columns in the DataFrame, including count, mean, standard deviation, minimum, 25th percentile (Q1), median (50th percentile), 75th percentile (Q3), and maximum values.

The output of `df.describe()` is a DataFrame where each row represents a statistical measure, and each column represents a numerical column in your DataFrame. The statistics provided include:

- `count` : The number of non-null values in each column.
- `mean` : The mean (average) value of each column.
- `std` : The standard deviation, which measures the dispersion of values in each column.
- `min` : The minimum value in each column.
- `25%` : The 25th percentile (Q1) value, which is the value below which 25% of the data falls.
- `50%` : The median value (50th percentile), which represents the middle value of the data.
- `75%` : The 75th percentile (Q3) value, which is the value below which 75% of the data falls.
- `max` : The maximum value in each column.

This summary is helpful for getting an initial understanding of the distribution and characteristics of your data. It can help you identify outliers, assess data central tendency, and recognize potential data issues or patterns.

H df[['Age', 'Orders', 'Amount']].describe()

G The `df[['Age', 'Orders', 'Amount']].describe()` command is used to generate descriptive statistics specifically for the columns 'Age,' 'Orders,' and 'Amount' in the DataFrame `df` . Here's what this command does:

- `df` : This is the DataFrame you've been working with.
- `[['Age', 'Orders', 'Amount']]` : The part of the command specifies a subset of columns from the DataFrame `df` . In this case, you are selecting only the 'Age,' 'Orders,' and 'Amount' columns for which you want to calculate descriptive statistics.
- `.describe()` : This is a method applied to the selected subset of columns. It computes summary statistics for the numerical columns in this subset, including count, mean, standard deviation, minimum, 25th percentile (Q1), median (50th percentile), 75th percentile (Q3), and maximum values.

percentile (25), and maximum values.

The output of `df2['Age', 'Dodoo', 'Amount'].describe()` will be a DataFrame where each row represents a statistical measure, and each column represents one of the selected columns ('Age', 'Dodoo', and 'Amount'). The statistics provided include:

- `count`: The number of non-null values in each of the selected columns.
- `mean`: The mean (average) value of each selected column.
- `std`: The standard deviation, which measures the dispersion of values in each selected column.
- `min`: The minimum value in each selected column.
- `25%`: The 25th percentile (Q1) value for each selected column, which is the value below which 25% of the data falls.
- `50%`: The median value (50th percentile) for each selected column, representing the middle value of the data.
- `75%`: The 75th percentile (Q3) value for each selected column, which is the value below which 75% of the data falls.
- `max`: The maximum value in each selected column.

This allows you to get specific summary statistics for the columns you are interested in, which can be helpful for a focused analysis of those particular attributes.

H

```
ax = sns.countplot(x='Gender',data = df)
```

The `ax = sns.countplot(x='Gender', data=df)` command is used to create a countplot visualization using the Seaborn library's `sns` in Python. Let's break down what each part of this command does:

- `ax`: This is a variable that is assigned the result of the `sns.countplot()` function. `ax` is often used to manipulate or further customize the plot if needed.
- `sns`: This is the Seaborn library, which is used for data visualization.
- `countplot()`: This is a Seaborn function used to create a countplot, which is a type of bar plot that displays the counts of observations in each category of a categorical variable.
- `x='Gender'`: This parameter specifies the variable to be plotted on the x-axis. In this case, you are plotting the 'Gender' column from the DataFrame `df` on the x-axis.
- `data=df`: This parameter specifies the DataFrame from which the data for the plot will be taken, which is `df` in this case.

When you execute `ax = sns.countplot(x='Gender', data=df)`, it will create a countplot showing the counts of each gender category (e.g., 'Male' and 'Female') in the 'Gender' column of your DataFrame `df`. The x-axis will represent the 'Gender' categories, and the height of the bars will represent the counts of each category.

You can further customize the plot using the `ax` variable if you want to adjust the appearance or add additional information to the visualization.

- 0:17 **H**

```
ax = sns.countplot(data = df, x = 'Age Group', hue = 'Gender')
```

for bars in ax.containers:
ax.bar_label(bars)

The code you provided is creating a countplot with Seaborn and then adding labels to the bars using a loop. Let's break down what each part of this code does:

1. `ax = sns.countplot(data=df, x='Age Group', hue='Gender')`:
   - This line creates a countplot using Seaborn.
   - `data=df`: Specifies the DataFrame `df` as the data source for the plot.
   - `x='Age Group'`: Sets the 'Age Group' column as the variable to be plotted on the x-axis.
   - `hue='Gender'`: Adds a hue parameter, which means the bars will be color-coded based on the 'Gender' column. Each age group's bar will have different colors corresponding to the 'Male' and 'Female' categories.
2. The next part of the code:

```
for bars in ax.containers:
    ax.bar_label(bars)
```

   - This loop iterates through the containers of the bars in the countplot.
   - `ax.containers` is a collection of the bar containers.
   - `ax.bar_label(bars)` adds labels to each bar based on their height (count).

So, when you execute this code, it will create a countplot that displays the counts of each 'Age Group' category, with bars color-coded by 'Gender ('Male' and 'Female'). Labels indicating the count of each category will be placed on the top of each bar, making it easier to see the precise count for each combination of 'Age Group' and 'Gender'.

H

```
# Total Amount vs Age Group
sales_age = df.groupby('Age Group').sum()[['Amount']].sort_values('Amount', ascending=False)

sns.barplot(x = 'Age Group',y= 'Amount',data = sales_age)
```

This code is creating a bar plot to visualize the total sales amount per age group. It does so by first aggregating and summing the 'Amount' column for each 'Age Group' and then creating a bar plot using Seaborn. Let's break down the code step by step:

1. `sales_age = df.groupby('Age Group').sum()[['Amount']].sort_values('Amount', ascending=False)`:
   - This line first groups the DataFrame `df` by the 'Age Group' column.
   - Then, it calculates the sum of the 'Amount' column within each group.
   - `ax.index=False`: This parameter ensures that the 'Age Group' values become part of the resulting DataFrame as a regular column, rather than being set as the index.
   - Finally, it sorts the resulting DataFrame in descending order based on the 'Amount' column and assigns it to the variable `sales_age`.
2. `sns.barplot(x='Age Group', y='Amount', data=sales_age)`:
   - This line creates a bar plot using Seaborn.
   - `x='Age Group'`: Sets the 'Age Group' column as the variable to be plotted on the x-axis.
   - `y='Amount'`: Sets the 'Amount' column as the variable to be plotted on the y-axis.
   - `data=sales_age`: Specifies the data source for the plot, which is the `sales_age` DataFrame generated in the previous step.

When you execute this code, it will generate a bar plot where each bar represents an 'Age Group', and the height of the bar represents the total sales amount for that age group. The bars will be sorted in descending order based on the total sales amount, so you can easily see which age group had the highest sales. This visualization provides an effective way to compare sales across different age groups.

H

```
# total number of orders from top 10 states

sales_state = df.groupby('State').sc_order-False('Orders').sort_values('Orders', ascending=False).head(10)

sns.set(rc={'figure.figsize':(25,5)})
sns.barplot(data = sales_state, x = 'State',y= 'Orders')
```

This code is creating a bar plot to visualize the total number of orders for the top 10 states. It first calculates the total number of orders for each state, then sorts the states in descending order by the number of orders, and finally creates the bar plot using Seaborn. Here's a breakdown of the code:

1. `sales_state = df.groupby('State').sc_order-False('Orders')['Amount'].sort_values(by='Orders', ascending=False).head(10)`:
   - This line groups the DataFrame `df` by the 'State' column.
   - Then, it calculates the sum of the 'Orders' column within each group.
   - `ax.index=False`: Ensures that the 'State' values become part of the resulting DataFrame as a regular column, rather than being set as the index.
   - Next, it sorts the resulting DataFrame in descending order based on the 'Orders' column.
   - Finally, it selects the top 10 states with the highest number of orders using `.head(10)` and assigns the result to the variable `sales_state`.
2. `sns.set(rc={'figure.figsize':(25,5)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 25 units wide and 5 units tall. It controls the dimensions of the plot.
3. `sns.barplot(data=sales_state, x='State', y='Orders')`:
   - This line creates a bar plot using Seaborn.
   - `data=sales_state`: Specifies the data source for the plot, which is the `sales_state` DataFrame generated in the previous step.
   - `x='State'`: Sets the 'State' column as the variable to be plotted on the x-axis.
   - `y='Orders'`: Sets the 'Orders' column as the variable to be plotted on the y-axis.

When you execute this code, it will generate a horizontal bar plot where each bar represents a state, and the length of the bar represents the total number of orders for that state. The bars will be sorted in descending order by the number of orders, allowing you to quickly identify the top-performing states in terms of order volume. The larger the bar, the higher the number of orders for that state.

H

```
# total amount/sales from top 10 states

sales_state = df.groupby('State').sc_order-False('Amount').sort_values(by='Amount', ascending=False).head(10)

sns.set(rc={'figure.figsize':(25,5)})
sns.barplot(data = sales_state, x = 'State',y= 'Amount')
```

This code is creating a bar plot to visualize the total sales amount for the top 10 states. It calculates the total sales amount for each state, sorts the states in descending order by sales amount, and then creates the bar plot using Seaborn. Here's a breakdown of the code:

1. `sales_state = df.groupby('State').sc_order-False('Amount').sort_values(by='Amount', ascending=False).head(10)`:
   - This line groups the DataFrame `df` by the 'State' column.
   - Then, it calculates the sum of the 'Amount' column within each group.
   - `ax.index=False`: Ensures that the 'State' values become part of the resulting DataFrame as a regular column, rather than being set as the index.
   - Next, it sorts the resulting DataFrame in descending order based on the 'Amount' column.
   - Finally, it selects the top 10 states with the highest total sales amount using `.head(10)` and assigns the result to the variable `sales_state`.
2. `sns.set(rc={'figure.figsize':(25,5)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 25 units wide and 5 units tall. It controls the dimensions of the plot.
3. `sns.barplot(data=sales_state, x='State', y='Amount')`:
   - This line creates a bar plot using Seaborn.
   - `data=sales_state`: Specifies the data source for the plot, which is the `sales_state` DataFrame generated in the previous step.
   - `x='State'`: Sets the 'State' column as the variable to be plotted on the x-axis.
   - `y='Amount'`: Sets the 'Amount' column as the variable to be plotted on the y-axis.

When you execute this code, it will generate a horizontal bar plot where each bar represents a state, and the length of the bar represents the total sales amount for that state. The bars will be sorted in descending order by sales amount, allowing you to quickly identify the top-performing states in terms of total sales. The larger the bar, the higher the total sales amount for that state.

H

```
sales_state = df.groupby('Marital_Status','Gender').sc_order-False('Amount').sort_values(by='Amount', ascending=False)

sns.set(rc={'figure.figsize':(6,5)})
sns.barplot(data = sales_state, x = 'Marital_Status',y= 'Amount',hue='Gender')
```

This code is creating a bar plot to visualize the total sales amount based on the combination of 'Marital_Status' and 'Gender' categories. It calculates the total sales amount for each unique combination of these two variables, sorts the combinations in descending order by sales amount, and then creates the bar plot using Seaborn with the 'Marital_Status' on the x-axis, 'Amount' on the y-axis, and color-coded by 'Gender' using the `hue` parameter. Here's a breakdown of the code:

1. `sales_state = df.groupby('Marital_Status', 'Gender').sc_order-False('Amount').sort_values(by='Amount', ascending=False)`:
   - This line groups the DataFrame `df` by both 'Marital_Status' and 'Gender' columns.
   - It calculates the sum of the 'Amount' column within each group.
   - `ax.index=False`: Ensures that the 'Marital_Status' and 'Gender' values become part of the resulting DataFrame as regular columns, rather than being set as the index.
   - The resulting DataFrame is sorted in descending order by the 'Amount' column, showing the combinations with the highest total sales at the top.
2. `sns.set(rc={'figure.figsize':(6,5)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 6 units wide and 5 units tall. It controls the dimensions of the plot.
3. `sns.barplot(data=sales_state, x='Marital_Status', y='Amount', hue='Gender')`:
   - This line creates a bar plot using Seaborn.
   - `data=sales_state`: Specifies the data source for the plot, which is the `sales_state` DataFrame generated in the previous step.
   - `x='Marital_Status'`: Sets the 'Marital_Status' column as the variable to be plotted on the x-axis.
   - `y='Amount'`: Sets the 'Amount' column as the variable to be plotted on the y-axis.
   - `hue='Gender'`: Adds a hue parameter, which means the bars will be color-coded based on the 'Gender' column. Each 'Marital_Status' category will have bars for 'Male' and 'Female' with different colors.

When you execute this code, it will generate a grouped bar plot where each 'Marital_Status' category is represented on the x-axis, and the height of the bars represents the total sales amount. Additionally, bars for 'Male' and 'Female' within each 'Marital_Status' category will be color-coded, allowing you to compare sales amounts by gender for each marital status.

H

```
ax = sns.countplot(data=df, x='Marital_Status')

sns.set(rc={'figure.figsize':(6,5)})
for bars in ax.containers:
    ax.bar_label(bars)
```

This code creates a countplot to visualize the distribution of 'Marital_Status' categories in your DataFrame `df`. It then adds labels to the bars to display the count of each category. Here's a breakdown of the code:

1. `ax = sns.countplot(data=df, x='Marital_Status')`:
   - This creates a countplot using Seaborn.
   - `data=df`: Specifies the data source for the plot, which is the DataFrame `df`.
   - `x='Marital_Status'`: Sets the 'Marital_Status' column as the variable to be plotted on the x-axis.
   - The variable `ax` is assigned to the resulting plot object, allowing you to manipulate or customize the plot further if needed.
2. `sns.set(rc={'figure.figsize':(6,5)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 6 units wide and 5 units tall. It controls the dimensions of the plot.
3. The following loop adds labels to the bars:

```
for bars in ax.containers:
    ax.bar_label(bars)
```

   - `ax.containers` is a collection of the bar containers in the countplot.
   - The loop iterates through these containers.
   - `ax.bar_label(bars)` adds labels to each bar based on their height (count).

When you execute this code, it will generate a countplot with 'Marital_Status' categories on the x-axis, and each bar will represent the count of a specific category. Labels indicating the count of each category will be added to the top of each bar, making it easier to see the distribution of marital statuses in your dataset.

H

```
sales_state = df.groupby('Occupation').sc_order-False('Amount').sort_values(by='Amount', ascending=False)

sns.set(rc={'figure.figsize':(25,5)})
sns.barplot(data = sales_state, x = 'Occupation',y= 'Amount')
```

This code is creating a bar plot to visualize the total sales amount for different occupations. It calculates the total sales amount for each unique occupation category, sorts the categories in descending order by sales amount, and then creates the bar plot using Seaborn with 'Occupation' on the x-axis and 'Amount' on the y-axis. Here's a breakdown of the code:

1. `sales_state = df.groupby('Occupation').sc_order-False('Amount').sort_values(by='Amount', ascending=False)`:
   - This line groups the DataFrame `df` by the 'Occupation' column.
   - It calculates the sum of the 'Amount' column within each group.
   - `ax.index=False`: Ensures that the 'Occupation' values become part of the resulting DataFrame as regular columns, rather than being set as the index.
   - The resulting DataFrame is sorted in descending order by the 'Amount' column, showing the occupations with the highest total sales at the top.
2. `sns.set(rc={'figure.figsize':(25,5)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 25 units wide and 5 units tall. It controls the dimensions of the plot.
3. `sns.barplot(data=sales_state, x='Occupation', y='Amount')`:
   - This line creates a bar plot using Seaborn.
   - `data=sales_state`: Specifies the data source for the plot, which is the `sales_state` DataFrame generated in the previous step.
   - `x='Occupation'`: Sets the 'Occupation' column as the variable to be plotted on the x-axis.
   - `y='Amount'`: Sets the 'Amount' column as the variable to be plotted on the y-axis.

When you execute this code, it will generate a horizontal bar plot where each bar represents an occupation, and the length of the bar represents the total sales amount for that occupation. The bars will be sorted in descending order by sales amount, allowing you to quickly identify the top-performing occupations in terms of total sales. The longer the bar, the higher the total sales amount for that occupation.

H

```
sns.set(rc={'figure.figsize':(25,5)})
ax = sns.countplot(data = df, x = 'Product_Category')

for bars in ax.containers:
    ax.bar_label(bars)
```

This code creates a countplot to visualize the distribution of products across different product categories in your DataFrame `df`. It then adds labels to the bars to display the count of each category. Here's a breakdown of the code:

1. `sns.set(rc={'figure.figsize':(25,5)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 25 units wide and 10 units tall. It controls the dimensions of the plot, making it larger for better visibility.
2. `ax = sns.countplot(data=df, x='Product_Category')`:
   - This line creates a countplot using Seaborn.
   - `data=df`: Specifies the data source for the plot, which is the DataFrame `df`.
   - `x='Product_Category'`: Sets the 'Product_Category' column as the variable to be plotted on the x-axis.
   - The variable `ax` is assigned to the resulting plot object, allowing you to manipulate or customize the plot further if needed.
3. The following loop adds labels to the bars:

```
for bars in ax.containers:
    ax.bar_label(bars)
```

   - `ax.containers` is a collection of the bar containers in the countplot.
   - The loop iterates through these containers.
   - `ax.bar_label(bars)` adds labels to each bar based on their height (count).

When you execute this code, it will generate a countplot with 'Product_Category' categories on the x-axis, and each bar will represent the count of products within a specific category. Labels indicating the count of each category will be added to the top of each bar, making it easier to see the distribution of products across different product categories in your dataset.

M

```
sales_state = df.groupby('Product_Category').as_index=False)
['Amount'].sum().sort_values(by='Amount', ascending=False).head(10)

sns.set(rc={'figure.figsize':(20,8)})
sns.barplot(data = sales_state, x = 'Product_Category',y='Amount')
```

This code is creating a bar plot to visualize the total sales amount for the top 10 product categories. It calculates the total sales amount for each unique product category, sorts the categories in descending order by sales amount, and then creates the bar plot using Seaborn with 'Product_Category' on the x-axis and 'Amount' on the y-axis. Here's a breakdown of the code:

1. `sales_state = df.groupby('Product_Category').as_index=False)['Amount'].sum().sort_values(by='Amount', ascending=False).head(10)`:
   - This line groups the DataFrame `df` by the 'Product_Category' column.
   - It calculates the sum of the 'Amount' column within each group.
   - `as_index=False`: Ensures that the 'Product_Category' values become part of the resulting DataFrame as regular columns, rather than being set as the index.
   - The resulting DataFrame is sorted in descending order by the 'Amount' column, showing the top 10 product categories with the highest total sales.
2. `sns.set(rc={'figure.figsize':(20,8)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 20 units wide and 16 units tall. It controls the dimensions of the plot, making it larger for better visibility.
3. `sns.barplot(data=sales_state, x='Product_Category', y='Amount')`:
   - This line creates a bar plot using Seaborn.
   - `data=sales_state`: Specifies the data source for the plot, which is the `sales_state` DataFrame generated in the previous step.
   - `x='Product_Category'`: Sets the 'Product_Category' column as the variable to be plotted on the x-axis.
   - `y='Amount'`: Sets the 'Amount' column as the variable to be plotted on the y-axis.

When you execute this code, it will generate a vertical bar plot where each bar represents a product category, and the height of the bar represents the total sales amount for that category. The bars will be sorted in descending order by sales amount, allowing you to quickly identify the top 10 product categories with the highest total sales. The taller the bar, the higher the total sales amount for that category.

M

```
sales_state = df.groupby('Product_ID').as_index=False)
['Orders'].sum().sort_values(by='Orders', ascending=False).head(5)

sns.set(rc={'figure.figsize':(20,8)})
sns.barplot(data = sales_state, x = 'Product_ID',y='Orders')
```

This code is creating a bar plot to visualize the total number of orders for the top 10 products (identified by 'Product_ID'). It calculates the total number of orders for each unique product, sorts the products in descending order by the number of orders, and then creates the bar plot using Seaborn with 'Product_ID' on the x-axis and 'Orders' on the y-axis. Here's a breakdown of the code:

1. `sales_state = df.groupby('Product_ID').as_index=False)['Orders'].sum().sort_values(by='Orders', ascending=False).head(10)`:
   - This line groups the DataFrame `df` by the 'Product_ID' column.
   - It calculates the sum of the 'Orders' column within each group.
   - `as_index=False`: Ensures that the 'Product_ID' values become part of the resulting DataFrame as regular columns, rather than being set as the index.
   - The resulting DataFrame is sorted in descending order by the 'Orders' column, showing the top 10 products with the highest number of orders.
2. `sns.set(rc={'figure.figsize':(20,8)})`:
   - This line sets the figure size for the upcoming Seaborn plot to be 20 units wide and 5 units tall. It controls the dimensions of the plot.
3. `sns.barplot(data=sales_state, x='Product_ID', y='Orders')`:
   - This line creates a bar plot using Seaborn.
   - `data=sales_state`: Specifies the data source for the plot, which is the `sales_state` DataFrame generated in the previous step.
   - `x='Product_ID'`: Sets the 'Product_ID' column as the variable to be plotted on the x-axis.
   - `y='Orders'`: Sets the 'Orders' column as the variable to be plotted on the y-axis.

When you execute this code, it will generate a horizontal bar plot where each bar represents a product (identified by 'Product_ID'), and the length of the bar represents the total number of orders for that product. The bars will be sorted in descending order by the number of orders, allowing you to quickly identify the top 10 products with the highest order volumes. The longer the bar, the higher the total number of orders for that product.
